ABSTRACT: For the operational starting of the Jules Horowitz material testing reactor (JHR) in France, CEA intends to promote different experimental devices aiming at testing materials and fuels under irradiation¹.

More specifically, in the safety studies domain, the LORELEI “Light water One Rod Equipment for LOCA Experimental Investigations” test device is dedicated to the study of the thermal-mechanical behavior of a fuel rod and quantification of Fission Product (FP) and fissile material releases under Loss Of Coolant Accident (LOCA) type conditions.

Lorelei will allow investigating ballooning and burst of the fuel cladding, clad corrosion phenomena (oxidation and hydriding), post quench behavior and FP release (for that aim, the device will be connected to water and gas sampling lines to the Fission Product Laboratory of the JHR).

This paper presents the scientific objectives of the Lorelei device, its main technical characteristics, its experimental protocol and the main options of the preliminary design, based on thermal-hydraulic and mechanical studies. Examinations planned on non-destructive underwater benches and characterization laboratories of the JHR will be detailed, in order to highlight their essential support for gaining as soon as possible exclusive and valuable scientific data on the “as tested” sample.

KEYWORDS: LOCA, LORELEI, MTR, JHR

I. INTRODUCTION

The development process of a fuel product or a nuclear material before using it at an industrial scale in a power reactor ranges from the characterization of the material itself under neutronic flux up to its qualification in accidental conditions. To support this process, irradiations in Material Testing Reactors (MTRs) are mandatory and are in practice the basis of the whole development process². Dedicated reactors play also an important complementary role for some specific integral tests (e.g. RIA test for fuels). Irradiations of precursors in power reactors are limited to products which present a slight design evolution (clad alloy, microstructure optimization, doped fuel, etc.) and which ensure an expected behavior quite comparable to the standard product. They are also used when a statistical approach is useful for defining a safety criterion.

The Jules Horowitz Material Testing Reactor (JHR MTR) which is under construction at the CEA Cadarache in France will be an important international User Facility for R&D in support to the nuclear industry, research centres, regulatory bodies and TSO, and academic institutions^{3, 4}. It represents a unique and extremely favourable situation for which future end-users can express very early their needs, thanks to either participation to the JHR Consortium, or to international programs or through bilateral collaborations⁵.

For the operational starting of the JHR, CEA intends to promote different experimental devices aiming at testing

materials and fuels under irradiation. More specifically, in the safety studies domain, CEA plans to propose a dedicated LOCA-type (Loss of Coolant Accident) device to its future customers. Implementation of such a family of experiments in the JHR will be based on a single effect experimental strategy and implemented on one (or a few) samples of limited length. It will integrate the local neutronic map, especially if the experiment is put at the research reactor core periphery or in the reflector. Finally results will be devoted in priority to:

- Understand mechanisms governing the fuel sample behavior during a LOCA, in particular at high burn-up,
- Quantify the radionuclide released fraction whatever the type of their chemical form (gaseous, volatile, semi- and non-volatile, and fissile material if any),
- Supply data and validate safety codes, and in particular, elemental models and laws.

The acronym of this device is LORELEI: Light water One Rod Equipment for LOCA Experimental Investigations. The design and manufacturing of the test device are made in collaboration with the “Israel Atomic Energy Commission” (IAEC). Lorelei is expected to be operational just after the JHR start-up.

This document describes the main scientific objectives and presents an experimental sequence designed to simulate a real loss of coolant accident which could occur in a power reactor. It also describes the main functions of the experimental device.

The phenomenology during such an accident is complex and many phenomena are involved. Among them, the following ones can be underlined:

- The thermal-hydraulics aspects: the pipe failure leads to the depressurization of the primary system with a high speed steam-water ejection at the breach (two phase flow, critical flow). In addition, the heat transfer coefficient on the cladding strongly changes during the transient: dry-out at the beginning of the accident, followed by almost adiabatic conditions and a re-increase of the heat transfers due to the safety injections, core re-flooding and quenching.

- The fuel rod thermal-mechanical behavior due to the high internal pressure and the high temperature transient (clad ballooning and burst), due to the clad high temperature corrosion (oxidation, hydriding), due to the remaining strength during the quench (differential expansion between the rod and the surrounding structures), but also due to the possible fuel evolution (fracturation or fragmentation, relocation, dispersal).

- The radio-isotope and fissile material releases (at the burst time, during the high temperature phase, and during the quench and post-quench phase).

II. GENERAL OBJECTIVES

The objectives of the Lorelei device are to focus on the thermal-mechanical behavior of the rod and to quantify fission product releases. It will not be designed to reproduce specific thermal-hydraulical aspects such as blow-down, dry-out or reflooding phases occurring during a real LOCA sequence.

The Lorelei device will mainly contribute to characterize new cladding materials, optimized or new fuel materials, new fuel assemblies design, new fuel management strategies (high burn-up, high duty) and the corresponding FP releases in LOCA situation and to investigate specific phenomena such as possible fuel relocation (within the rod and out-of the rod), impact of grids on fuel relocation, etc. The experimental fuel rod itself shall have a realistic internal gaseous energetic load (i.e. plenum volume and filling pressure related to the fissile stack length).

Moreover, and beyond LOCA issues, following the Fukushima events, there is an increasing international interest to evaluate some alternative cladding materials which could give some additional margins upon LOCA conditions and beyond for LWRs. Specific tests have thus to be defined to address this issue in the future.

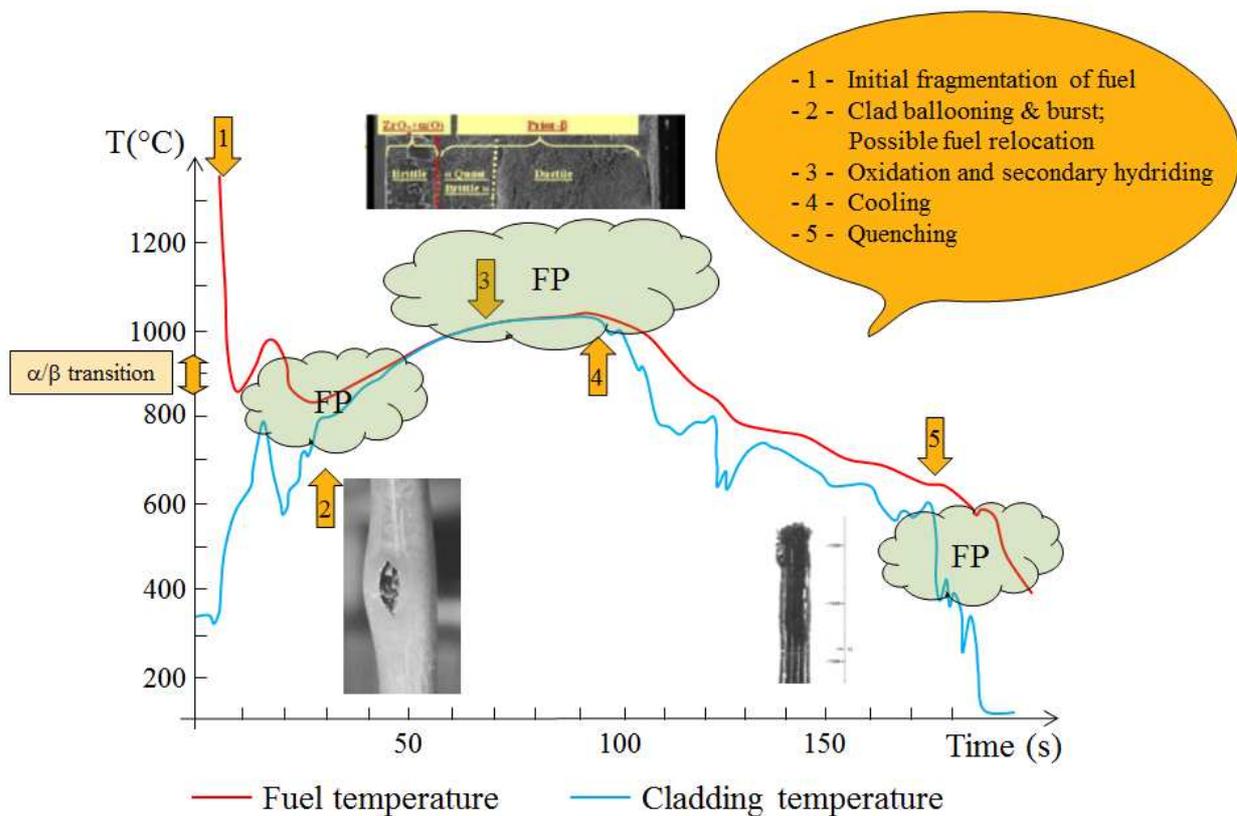

Fig. 1. Phases of the LOCA sequence

During a typical “large breach” LOCA sequence, several phenomena can be observed on a fuel rod (see figure 1):

- The reactor shutdown initially provokes a dramatic

drop of the fuel pellet central temperature and a flattening of the radial temperature profile due to a quasi-isothermal behavior (very bad thermal exchange with the primary steam).

- The rise in temperature and the pressure decrease in the primary circuit lead to the ballooning of the clad after phase transformation. This generally leads to the failure of the clad at a temperature ranging from 700 to 900°C. This failure is accompanied by a first burst of fission product release (mainly noble gases).

- A large change in the fuel stack geometry can occur, with filling of the balloon with fuel grains,

- A temperature equilibrium is reached at a value about 1000 to 1200°C, and a temperature plateau lasts a few tens of seconds with a very flat radial profile in the fuel pellet,

- The cladding oxidation phase occurs significantly during this high temperature plateau, between 1000 and 1200°C, and leads to:

- The development of a supplementary oxide layer over a subjacent oxide layer with high oxygen content.

- The production of hydrogen. One part of it can interact with metal (hydriding).

- The resulting clad embrittlement.

- Heat emission.

- The cooling/quenching phase can lead to the brittle fracture of the clad by thermal shock if the corrosion thickness or the hydride local concentrations are large enough. This embrittlement, together with liquid water ingress in the balloon, is accompanied by a supplementary fission product and sometimes actinides release.

Such sequence is a strong challenge for a relevant assessment of phenomena:

- A correct assessment of the representative cladding creep-ballooning and burst and its resistance to fragmentation during or after the final quenching is an important issue. Dedicated on-line and/or post-LOCA transient thermal-mechanical tests together with deep microstructural & microchemical post-quenching characterization of the cladding materials have to be developed. The objective is to derive a physics based relationship between the actual cladding mechanical properties and its residual microstructure, during and/or after LOCA transient tests,

- The chemical and mechanical interactions between the fuel pellet and the cladding tube is also an important issue and more studies have to be done to get better insights into the potential fuel relocation and dispersal.

III. DEVICE MAIN CHARACTERISTICS

1. Description of the in-pile components

The in-pile part of the device will be installed in a water channel of the reflector (see figure 2). The water channel will be equipped with a displacement system allowing a radial movement of about 45 cm. The power is therefore controlled by the distance between the sample and the core vessel. The progression of the displacement system will be limited by an adjustable mechanical stop block to prevent any movement towards the reactor beyond a certain distance, thereby limiting the power generated in the fuel rod.

The in-pile device is connected to a device holder which is fixed on the displacement system. An anti-fly off system will be positioned on the top of the device and fixed to the displacement system to prevent any vertical movement of the in-pile device which could follow some specific accidental

sequences with a quick coolant circuit depressurization.

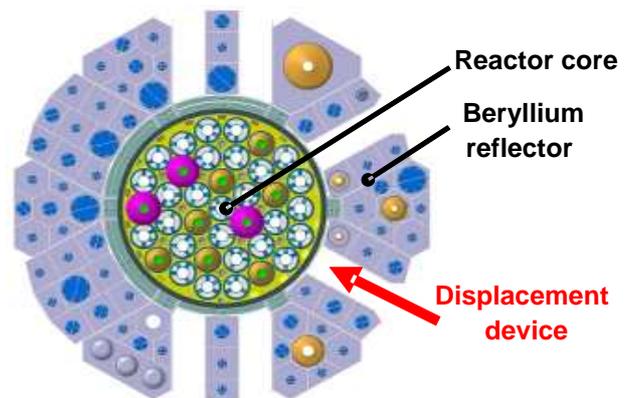

Fig. 2. Location of the Lorelei device in the reflector

The in-pile device has been designed to work as a closed capsule where the fuel rod is cooled in natural convection with a single phase thermo-siphon circulating inside the device.

The device presents a change in diameter in the middle of its vertical axis (see figure 3). The lower part of the device, with the smaller diameter, contains the fuel rod and is in the under neutron flux area. The upper part, with the bigger diameter, is above the neutron flux zone and plays the role of a heat exchanger where the power generated in the lower part is transferred to the cooling water surrounding the outer flask. This two diameters shape limits power generation volume in the under flux area and offers high heat transfer area in the upper part.

The in-pile device is bounded by a double flask made of stainless steel. The inner flask is a pressure flask designed to withstand the internal pressure while the outer flask is only a second envelope whose function is mainly to form a gas gap. This gap is filled with helium and plays the role of thermal insulation between the hot inner parts and the water of the pool surrounding the device. Monitoring the pressure in the gas gap will also be used to detect potential leakage in the flasks. The gas gap is thin in the upper part (0.5 mm), where no deformations are expected, to increase the heat transfer toward the pool. The gas gap is thicker in the lower part (1 mm) where mechanical structures are expected to bend because of azimuthal thermal gradient.

The fuel sample is held by a sample holder at the center of the device. A flow separation tube is installed in the flask, forming two concentric channels, a hot channel surrounding the fuel sample and a cold channel between the separator and the inner flask. Thanks to this separation, a thermosiphon can build up ensuring the cooling of the fuel rod during the re-irradiation phase before the LOCA transient starting.

The flow separator integrates a peripheral heater which is used to create adiabatic conditions for the fuel during the adiabatic heating phase (see IV.2).

The gap between the device holder and the outer flask forms a cooling channel where the water coming from the pool flows in forced convection using an independent on-board pump on the displacement system.

A neutron hafnium screen will be fixed on the inner side of the device holder and will be used to flatten the axial flux up

to 40 cm height.

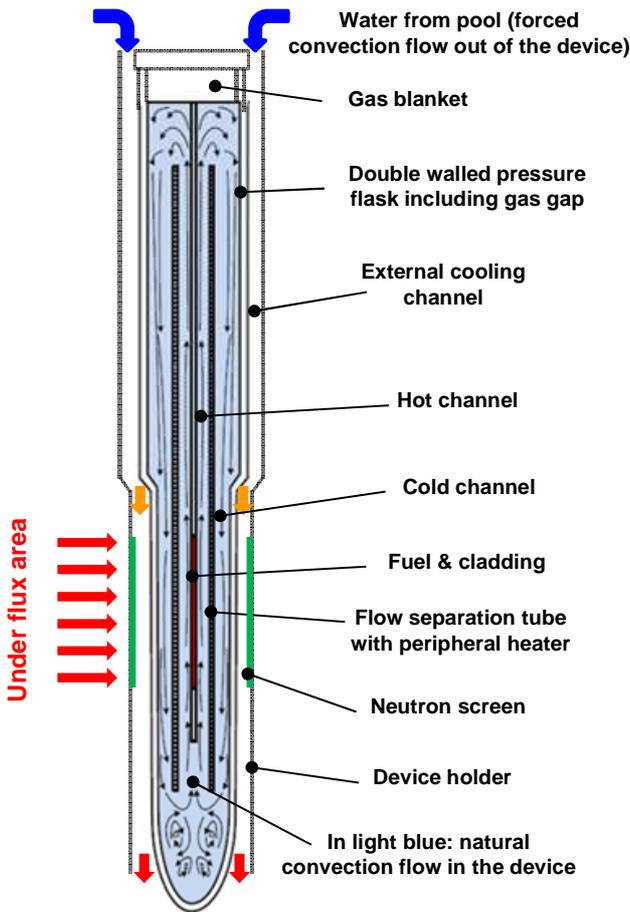

Fig. 3. Thermosiphon flow during re-irradiation

Instrumentation will be implemented in order to monitor temperature and pressure in different parts of the device and at each step of the experimental sequence. The top of the fuel sample holder axial displacement will also be measured. Based on the axial displacement measurement and thermal expansion computations, an estimation of the specimen total elongation will be predicted.

2. Device layout outside the reactor pool (see figure 4)

The Lorelei device will be connected to a devoted cubicle through under water hydraulical and electrical lines. This out-of-pile equipment will be designed to insure the initial configuration of the loop, to control the emptying and reflooding phases.

The Lorelei device will also be connected to the Fission Products laboratory where all the contaminated fluids will be directed, analyzed and partly sampled at the end of the test. One sampling line, located at the bottom of the device will be used for water and one sampling line, at the top of the vessel, will be used for gas.

The Lorelei cubicle will also be used to store contaminated gases and liquids which have been sent through the FP laboratory. These fluids will be stored in different vessels depending on their contamination levels.

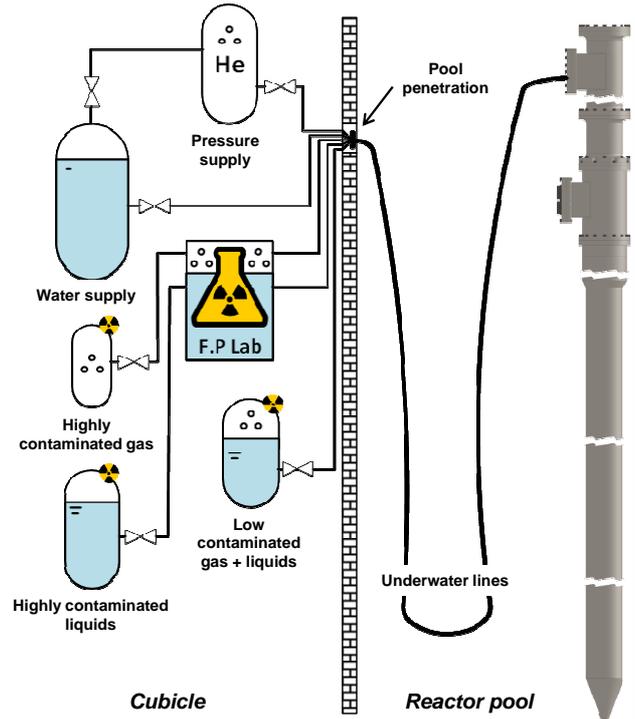

Fig. 4. Schematic layout outside the reactor pool

IV. EXPERIMENTAL PHASES

The main steps of the experimental sequence are illustrated in figure 5 and are presented below.

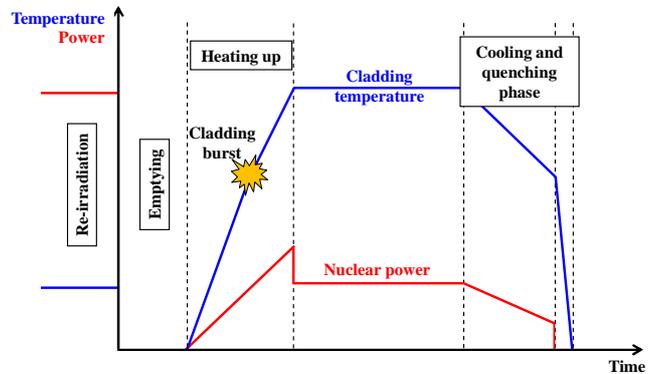

Fig. 5. Phases of the LOCA sequence

1. Re-irradiation

Before the “LOCA transient”, the test device is filled with water and operated as a capsule in natural convection (single phase thermo-siphon) in order to re-irradiate the fuel sample. A volume of helium is located above the water level, as a gas blanket, and is pressurized to set the static pressure (about 70 bars). During this phase, fluids can be sampled to check the tightness of the cladding.

The device will be irradiated at low power for a few days in order to generate detectable short half-life fission products. This will lead to a possible non-representative inventory and distribution for some FPs but it will be possible to detect all the fission products even in the case of a high burn-up rod test. As an example, the detected activity

(counting rate) of the short half-life ^{131}I will be of the same amplitude than the long half-life ^{137}Cs .

The nominal linear power of the re-irradiation will be about 30 W/cm. The device will, however, be designed to withstand a much higher linear power of about 100 W/cm.

2. LOCA sequence

Following dewatering (draining the water out of the device by injecting gas), the pressure inside the device will be limited to a few bars. Therefore, in order to avoid boiling in the device the water will be cooled down before emptying by moving the displacement device to back position. A small amount of water will remain at the bottom of the device in order to provide a saturated steam atmosphere during the dry phase sequence. The steam will be generated by an electrical heater located at the bottom of the flask. A debris catcher will also be fitted near the bottom of the device in order to retrieve fuel particles (if any) without hampering steam generation.

The temperature heat-up rate will be adjusted by controlling the position of the displacement system. It will range between 5 and 10°C/s up to cladding failure. The initial internal fuel sample pressure will be a test parameter that can be adjusted while preparing the specimen before every experiment, depending on the expected ballooning and burst conditions. In order to avoid peripheral temperature discrepancies and to insure adiabatic conditions, a peripheral electrical heater is implemented in the flow separator to compensate for peripheral differences in thermal insulation and thermal inertia. The azimuthal cladding temperature difference is expected to be less than 10°C.

The peripheral heater will be stopped after clad burst or when reaching 900°C in order to increase the apparent heat-losses of the rod and to avoid the steam - Zircaloy thermal escalation. The temperature heat-up will go on until reaching the high-temperature plateau. The high temperature plateau will be reached as fast as possible, without increasing the heating rate above its specified value during the adiabatic heating phase and with a minimum temperature overshoot.

The cladding temperature will be stabilized at a predefined value selected in the range [1000, 1300°C] by adapting the nuclear power in the experimental sample. In this phase the oxidation reaction will be studied and the duration of this phase will be set according to preliminary estimation of the amount of Zirconium that will be reacted. The maximum cladding temperature will be maintained below 1550°C under all conditions by safety actions, which will exclude the possibility of cladding and fuel melting.

At the end of the plateau, the cooling of the device will first rely on heat losses by moving the displacement device backward to reduce the nuclear power. The fuel will be cooled passively at a rate of -1 to -10°C/s.

The quenching phase will then be instigated by injecting cold water from the bottom of the device. It will include the loading of the fuel sample during the quenching and just after the quenching (tensile loading of about 200N, 500N max). The reflooding will be initiated when reaching a pre-defined cladding temperature between 800 and 1200°C. The internal pressure flask will be designed to resist the pressure peaks associated with this phase.

After quenching, it will be possible to operate in the

long term (several hours or days) at low power in order to study the post-quench fuel behaviour. The pressure in the device will be low, up to 10 bars and the LHGR will be up to 5 W/cm. After test end, the device will be emptied: reflooding water then upper gas blanket will be transferred to the LORELEI cubicle thanks to liquid and gas sampling lines. These lines will be connected to the FP laboratory in order to quantify fission products and fuel particles releases through on-line fluid monitoring and delayed measurements on samples (radioactive and atoms countings).

3. On-site post-irradiation examinations

The essential supports of some JHR analysis laboratories and on-site non-destructive examination benches have to be highlighted because they greatly contribute to the quality of the experimental process⁶:

- A fission product laboratory for welcoming and measuring fluids (gas + steam blanket and liquid after quenching) in contact with the tested rod during and after the LOCA-type sequence, either on-line during the fluid transferring between the test section and the FP Laboratory, or after sampling. For this last item, the target is to maximize the number of measured radioactive isotopes by detecting short half-lives as low as about one hour (e.g. ^{87}Kr , 76 min),

- A chemistry laboratory, for delayed measurements on samples for counting stable and radioactive isotopes, or for preparing samples (e.g. partitioning) for a specific analysis (alpha spectrometry etc.)

- High performance non-destructive examinations benches, based on photon imaging techniques: X-tomography by transmission and gamma scanning and tomography by emission will be coupled and implemented on the same underwater bench. The handling process has to be capable to welcome quickly and with a minimized handling the irradiation device containing the degraded rod. The goal is to obtain i) a precise image of the sample "as tested" (e.g. fuel stack fragmentation and delocalisation status) without later evolution or issues caused by a transportation and ii) to be able to set up the complete and quantitative balance of fission products in the in-pile test section: FP remaining in the rod, deposited on the device walls or concentrated at the bottom part. Here the target is to be able to start the gamma scanning sequence roughly a dozen hours after the end of the test (this delay includes fluid transfers).

After that, the sample, the sample-holder and the test section will be filled with a metallic alloy in JHR hot cell for preserving at the best the sample status during the transportation to the hot cell laboratory. Micro-analyses on fuel and cladding are then planned after cutting and recovering the sample.

V. Focuses on the LORELEI design

The Lorelei project requires multi-disciplinary research, development and engineering, such as nuclear physics, mechanical engineering, thermal-hydraulics, material engineering, instrumentation and control and so on.

The major challenges in the roadmap toward the design are:

- Defining a closed capsule that can operate as a thermo-siphon during the re-irradiation phase and that can also reproduce all LOCA-type transient sequence phases. A thermo-siphon at re-irradiation phase should be able to remove nominal power with an operational margin of 3.3. The complexity of the flow field in the LORELEI test device, as a closed-loop thermo-siphon, is due to the opposing forces in the device - buoyancy forces and natural convection flow generated by the fuel power in the hot channel, opposed by buoyancy forces generated by non-uniform gamma power generated in the device structure. Figure 6 shows the results of a CFD numerical simulation of the conjugated turbulent natural convection and heat transfer in a 3D geometry⁷.

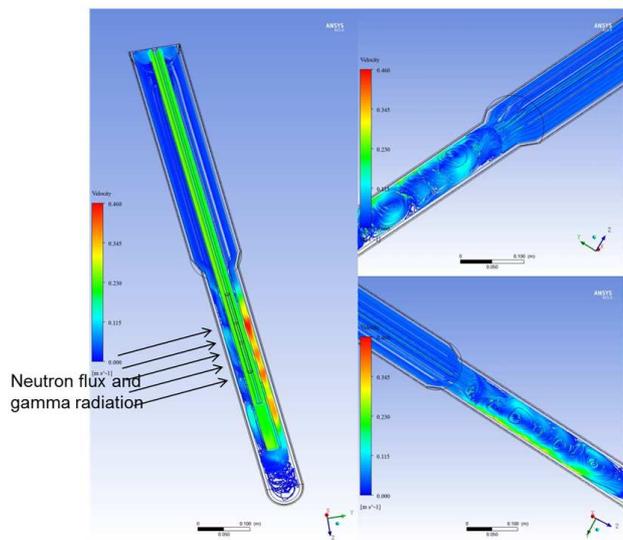

Fig. 6. Stream lines during the re-irradiation phase

- Controlling the flask distortion resulting from asymmetrical gamma radiation heating and consecutive azimuthal temperature distribution.
- Developing a high power density and high temperature peripheral heating element which is used to ensure adiabatic conditions during the heat up phase. A prototype has been internally built and tested to validate the design.
- Performing indirect temperature measurement in a hostile environment (steam and temperature) without disturbing the mechanical behavior of the cladding, especially as regards ballooning and burst.
- Integrating numerous components and sensors in a very limited space (needle geometry: more than 3 meters long for a 10 cm outer diameter). Fortunately the preliminary design⁸ (see figure 7) showed that it is possible to ensure all the required scientific objectives.

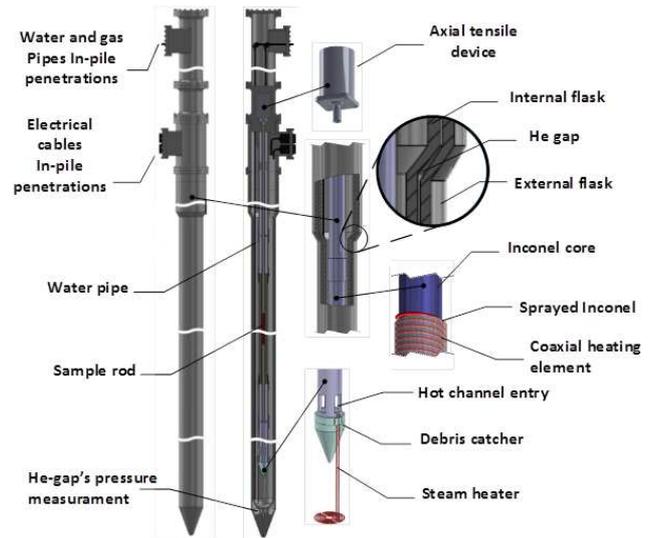

Fig. 7. Lorelei preliminary design

- Performing a safety oriented design: reliability in the measurements, passive cooling within the device, inherent prevention of temperature escalation by high thermal losses, double walled flask and piping and so on.

VI. CONCLUSIONS

The objective of the LORELEI device is to implement high quality LOCA-type sequences for testing new fuels and materials (e.g. enhanced accident tolerant fuels), for solving pending issues on LOCA phenomenology, and for improving experimental data range and accuracy for codes and models validation. These targets will be reached thanks to the services offered by the JHR, a new MTR designed in a modern safety frame: an irradiation device highly instrumented, modern analysis laboratories and on-site non-destructive examination benches allowing high-performance gamma and X tomographies on a routine basis.

This document describes the Lorelei device, one of the JHR fuel devices, its main scientific objectives and its main functions. It also presents the experimental sequence designed to simulate a real loss of coolant accident which could occur in a power reactor. The major challenges in the roadmap toward the design have also been briefly explained. The feasibility of the project has been demonstrated and early 2014, Lorelei just entered in its detailed design phase. The beginning of manufacturing is expected for the beginning of 2016.
